Chapter 1

Introduction

The IMS Corpus Workbench is a set of tools for the manipulation of large, linguistically annotated text corpora. One of the tools is the IMS Corpus Query Processor CQP, a specialized search engine for linguistic research.

This manual explains how information can be extracted from text corpora by the use of the CQP-query language and by some additional commands and parameters. CQP assumes that corpora have been indexed beforehand. The indexing and general administration of corpora is described in a separate volume, the CQP-Administrator's Manual [2]. The philosophy and the overall architecture of the Corpus Workbench has been presented in [1, 3].

1.1 Corpora, Annotations, Queries, and Results

The most basic version of a text corpus (or corpus) is just a sequence of words (or tokens). An individual occurrence of a word determines a corpus position (which could be represented by a number). In order to make a corpus more useful for linguistic analysis, a corpus can be annotated at least in three dimensions.

Positional annotation

The individual corpus positions can be annotated with any number of positional attributes like part-of-speech (POS) information, morphosyntactic information, base forms (lemmata), ....

Structural annotation

Structural attributes can be inserted into the corpus, e.g. paragraph or sentence boundaries or even more fine-grained phrase boundaries.

Multilevel annotation

A corpus can be aligned with another corpus, e.g. with its translation, or with other representations of the sequence of tokens, e.g. with its intonation patterns or discourse relations. Multilevel annotation of corpora can be seen as a generalization of (hierarchical) structural annotation, since it must be possible to associate overlapping and/or non-adjacent sections of two corpora or annotation levels.
In our philosophy, we use the term *corpus* as a shorthand for *annotated corpus*.

*CQP* allows for *queries* to corpora along the above mentioned dimensions, at least to a certain extent:

Access to positional annotations

**Single corpus positions**

The values of positional attributes (where *word* is just one, prominent attribute) can be queried by regular expressions over characters. Constraints on different attributes for the same corpus position can be combined into Boolean expressions.

**Sequences of corpus positions**

Queries to single corpus positions can be embedded into Boolean expressions over regular expressions (over corpus positions) in order to describe sequences of corpus positions.

Access to structural annotations

Structural annotations are treated like corpus positions, i.e. they can be part of a query to a sequence of corpus positions. However, neither recursively embedded nor overlapping annotations are supported by *CQP*.

Access to multilevel annotations

*CQP* supports queries to aligned corpora.

In *CQP*, the *result* of a query is the list of *corpus intervals* which match the given query. Such a corpus interval is also called a *match*. In a sense, queries define additional structural boundaries on a corpus, the so-called *ad-hoc structures*. These ad-hoc structures can be referred to in subsequent queries, due to the concept of *query names*. Named queries are the basis for incremental corpus exploration.

Query results can be displayed as plain text, HTML, or LaTeX - with or without the corresponding corpus annotations. In addition, *CQP* supports the alphabetical and frequency-based sorting of query results.

1.2 Organization of this manual

This manual is organized as follows. The next chapter 2 describes the basic commands of *CQP*. The following chapters introduce the query language of *CQP*: access to single corpus positions (chapter 3), to sequences of corpus positions (chapter 4), to structural attributes (chapter 5), and to aligned corpora (chapter 6). The manual concludes with the description of the sorting routines of *CQP* (chapter 7).
Chapter 2

Basic interaction with CQP

This chapter explains how to call the CQP-system and how to leave it again. It tells how a corpus can be selected, gives a sample query, and explains how to display and save query results.

2.1 Starting and leaving CQP

CQP is started by simply typing the command

    cqp

at the shell prompt. There are a number of command line options and Unix system variables which affect the behavior of cqp. These are described in appendix A. You leave CQP simply by typing

    exit;

or by using Control-D as a shortcut.

2.2 Selecting a corpus

Before you can run a query, you have to select a corpus. You can find out which system corpora are accessible by typing the CQP command

    show system;

or short:

    show;

In the case that you cannot find the corpus for which you are looking, please check the paths of the corpus registries, i.e. the CQP system variable Registry, by typing
set Registry

You can remedy the situation for the current CQP session by changing the value of the Registry variable. E.g., if your corpus registries are located in the directories /corpora/registry and ~/registry then you have to issue the command (see also section A.1):

set Registry "/corpora/registry:/registry";

If you are lucky, your corpus administrators have provided some corpus information. Typically, this information consists of a copyright notice, a description of the corpus annotation and of the composition of the corpus. E.g., for the corpus named BNC, CQP will display this kind of information (if available) if you use the info-command in the following manner:

info BNC;

Note: Each CQP command must be completed with a semicolon!

In order to select a corpus, say UP, which is the part-of-speech tagged Penn Treebank corpus of the University of Pennsylvania, just enter

UP;

If the corpus is not available, CQP will return an error message. After the successful selection of the corpus UP, the command line prompt of CQP changes to

UP>

This means that the next query will be evaluated on that corpus.

2.3 A simple query

If you want to look for a single word, say "Clinton", just type "Clinton" at the CQP prompt.

UP> "Clinton";

The double quotes are important! Within the double quotes, case and blanks are significant!

After a short time you get the following output:

44963: Utah, $ 15,000 fine; <Clinton> P. Hayne, New Orleans, $ 7,500 fine
653115: n education, Gov. Bill <Clinton> of Arkansas announced that "this

This output is called the *result* of the query. It consists of a list of individual lines. Each line has the following shape: The angle brackets `<...>` mark the *corpus interval* which matches the query, for short, the *match*. The text on both sides of the match is called the *context* of the match. Historically, this output format of concordances is called *kwic format* which stands for *keyword in context*. In our example, the keyword is “Clinton”. In CQP, kwic lines should rather be called ‘match in context’ since CQP search is not restricted to single corpus positions.

### 2.4 Displaying a query result

This section tells you how to display query results and other CQP-interaction. CQP allows for changing the browsing method, the size of the result, the size of context, the display of annotations, and the text filters for the output to a file.

#### 2.4.1 Setting the *AutoShow* system variable

It depends on the value of the CQP *system variable* `AutoShow` whether a query result is displayed immediately after the evaluation of the query, or only on demand. One of the numerous applications of the `set`-command is to show the contents of a system variable. The command

```
set;
```

or more precisely

```
set AutoShow;
```

or, since case doesn’t matter in this case:

```
set autoshow;
```

will tell you, whether `AutoShow` has been switched on or off. The set of legal values for *flag-like system variables* is usually the following: *yes*, *no*, *on*, *off*. So, in the case that you don’t want to see the query results automatically, say

```
set autoshow no;
```

`AutoShow` can be switched on again by

```
set autoshow yes;
```
2.4.2 Basic display method

Unless the system variable \texttt{AutoShow} has been switched off (see section 2.4.1), the result of a query is shown immediately after the evaluation of the query. If the variable has been switched off, or if you have got lost in a lengthy query result, the result of the last query can be displayed (again) by the \texttt{cat}-command:

\begin{verbatim}
cat;
\end{verbatim}

or

\begin{verbatim}
cat Last;
\end{verbatim}

Last is the \textit{query name} which is associated automatically with the most recent query.

2.4.3 Changing the browsing method

If the \texttt{CQP} variable \texttt{Paging} has been switched to \texttt{yes}, the output of the \texttt{cat} command will be sent to the Unix browsing tool which is defined by the \texttt{CQP} variable \texttt{Pager}. The output of the \texttt{cat} command is flushed to the screen, without user interaction, if \texttt{Paging} has been desactivated by the command:

\begin{verbatim}
set Paging no;
\end{verbatim}

You can choose another pager program, e.g. the \texttt{more} program, by changing the value of the \texttt{Pager} variable (see also section A.1).

\begin{verbatim}
set Pager more;
\end{verbatim}

You can switch off the \textit{highlighting} of matches by setting the value of the \texttt{Highlighting} variable, appropriately.

\begin{verbatim}
set Highlighting no;
\end{verbatim}

2.4.4 Restricting the size of the result

Often, the number of matches is enormous, so the user may be satisfied to see only a few matches. For this purpose, the \texttt{cut} and the \texttt{reduce} operators have been introduced.

\textbf{Restricted search}

The \texttt{cut} operator takes a query on its left side and a positive integer \texttt{n} on its right side, i.e.

\begin{verbatim}
Query cut n;
\end{verbatim}

Only the \texttt{n} initial matches of the query result will be calculated. For example, the result of the following query will be cut after 10 matches.

"Bill" cut 10;
Random reduction of a result

The reduce operator applies after the computation of a query result. It randomly reduces the query result to either a given number of concordance lines or to a certain percentage. For example, the statements

reduce to 5;

or

reduce Last to 5;

will discard all but 5 randomly selected lines from the last query result.

reduce to 10%;

or

reduce Last to 10%;

will randomly discard all but 10% of the matches from the last query result. In order to see the effect, you have to have displayed the, now reduced query result, once more (see section 2.4.2).

2.4.5 Changing the context size

The size of the context on the left and the right side of a match can be adapted by manipulating the CQP variables LeftContext, RightContext, and Context.

The following command will set the context on each side of the match to five characters.

set Context 5;

This is equivalent to

set LeftContext 5;
set RightContext 5;

If you mean five words, you must mention that explicitly.

set Context 5 word;

If your text comes with structural attributes, for example with the structural attribute s, you may have the context extended to the next s tag by stating:

set Context 1 s;
2.4.6 Displaying corpus annotations

Positional attributes

Say, if the corpus you work on has been annotated with a pos-attribute (part-of-speech annotation), you can switch on the display of that attribute by

```
show +pos;
```

Similarly for other attributes like lemma, ....

After that, the result for our simple query

"Clinton";

will be shown with the pos-annotation.

```
4963: /$ 15,000/CD fine/NN ;/: <Clinton/NP> P./NP Hayne/NP ,/, New/N
65315: n/NN ,/, Gov./NP Bill/NP <Clinton/NP> of/IN Arkansas/NP announ
653153: N ./SENT What/WP Gov./NP <Clinton/NP> is/VBZ advocating/VBG ,/
...
```

The display of the pos-attribute is switched off by the obvious command

```
show -pos;
```

If the display of all attributes has been switched off, or hasn’t been set at all, only the word forms of the corpus will be shown.

Structural attributes

The display of structural attributes can be switched on in a similar manner as the positional attributes. If s is a structural attribute of the current corpus, its display is switched on by

```
show +s;
```

and switched off by

```
show -s;
```

If the structural attributes s and article have values, these values will be displayed in the query result after having issued the command:

```
set PrintStructures "s,article";
```

The display of tag values is switched off by

```
set PrintStructures ""
```
Multilevel annotation

For a corpus HANSARD-E, which is aligned e.g. on the sentence with its translation HANSARD-F, CQP shows the aligned contexts if you issue the appropriate show command.

show +hansard-f;

Note that, for some reasons, here, the command is case-sensitive and expects the name of the aligned corpus in lower-case letters!

The display of the aligned contexts is switched off by

show -hansard-f;

2.4.7 Sending a result to a file or a Unix pipe

The output of the cat command can be redirected to a file /tmp/myResult by the following commands.

cat > "/tmp/myResult";

cat Last > "/tmp/myResult";

This version of the command will overwrite the file /tmp/myResult if it already exists. If you want to append the query result to an existing file, you have to use

cat >> "/tmp/myResult";

The cat command is not intended to work for system corpora since it does not make sense to copy a whole corpus. Use the appropriate low-level commands of CQP instead which have been described [2]!

Redirection to a Unix pipe is possible, as well. For example

cat > "| a2ps -8 | lpr";

will pass the output to the ASCII-to-Postscript converter and afterwards to the printer. The append mode (>>) must not be used for output into pipes.

Paging is disabled during output to files or to pipes.
Print modes
If you want to insert query results into a publication, it is convenient to have CQP produce the result in a useful format like \LaTeX code. (This option has been added in release 2.3.) This change of output format is caused by a \texttt{set PrintMode} command:

\verbatim
set PrintMode latex;
\endverbatim

Instead of 'latex', there are also the values html, sgml, and ascii. The latter is the default output format of CQP. So, in order to get rid of the \LaTeX or HTML formatting commands again, just say:

\verbatim
set PrintMode ascii;
\endverbatim

Print options
Since CQP wants to be nice and informative, the file created by the \texttt{cat>} command will start with a file header. This header includes the query, size of the query result, etc. You can create headerless files due to the command

\verbatim
set PrintOptions noheader;
\endverbatim

The header is switched on again with a command where the no-prefix is left out:

\verbatim
set PrintOptions header;
\endverbatim

With the print option \texttt{number}, the result lines will be numbered.

\verbatim
set PrintOptions number;
\endverbatim

For the \texttt{PrintMode ascii}, the left and right match delimiters can be adapted to the user’s personal taste.

\verbatim
set LeftKWICDelim "[";
set RightKWICDelim "]";
\endverbatim

In the case of html output (\texttt{PrintMode html}), there are also the print options \texttt{table} for creating an HTML table, \texttt{border} for inserting borders into HTML tables, and \texttt{wrap} for the wrapping of cells in HTML tables.

Several options can be set simultaneously if the list of values is inserted into quotation marks, e.g.

\verbatim
set PrintMode html;
set PrintOptions "table,border,wrap";
\endverbatim
2.5 Profiling

2.5.1 Evaluation time

The computation time for a query will be shown if the Timing variable has been switched on.

set Timing yes;

2.5.2 User interaction

CQP will protocol automatically your interactive input to CQP, if you set the CQP variable HistoryFile to a file name

set HistoryFile "/tmp/myHistory";

and switch on the WriteHistory flag

set WriteHistory yes;

The history file will be re-opened each time a user interaction has been completed and will be closed afterwards, so that the history should survive a CQP crash.

CQP commands which have been read from a file (see appendix A) will not be protocolled in the history file.

2.5.3 Warnings and messages

CQP warnings and messages can be switched off by changing the value of the Silent variable:

set Silent yes;

For the interactive use of CQP, you'd better make sure that Silent is set to no:

set Silent no;
Chapter 3

Access to single corpus positions

This chapter explains the syntax of CQP-queries which refer to single corpus positions.

3.1 Representations of characters

For special characters such as the German umlauts, there are two representations. You can use the \ followed by the octal code of that character (in the character set of the corpus!), e.g.

"Sp\344tzle";

This query will retrieve occurrences of the South-West German word Spätzle. Alternatively, the \TEX format of the special character can be used (see appendix B).

"Sp"atzle";

As the above example indicates, a character such as the quotation mark which has a special meaning in CQP is interpreted literally if it is preceded by the backslash \.

Note that all characters between the double quotes count! E.g. the two queries

"Clinton";

"Clinton ";

are not identical since the second one requires the blank character to appear as the final character of the string!

3.2 Regular expressions over characters

If you do not know exactly how a word is spelled in the corpus, you can leave the spelling of the word 'underspecified' by stating a regular expression. CQP has adopted the POSIX egrep notation of regular expressions. This comprises the following operations: parentheses for marking embedded expressions, concatenation, disjunction, lists of alternative characters, unspecified character, optionality, Kleene star, and Kleene plus. Certain types of regular expressions can be abbreviated by the use of a 'flag'.
3.2.1 Embedded regular expressions

Subsequently, it may be necessary to mark embedded regular expressions. For this purpose, parentheses (,) are used.

3.2.2 Concatenation

Even the simple query like

"Clinton";

is an instance of a regular expression. It is formed by the concatenation of the characters C, l, i, n, t, o, and n. Concatenation is expressed by the juxtaposition of regular expressions.

3.2.3 Disjunction

Let's assume, that we want to find the occurrences of the English word “the”, but we do want both, upper and lower case occurrences. This query can be expressed as

"(the)|The";

Here, the disjunction operator | lets CQP look for occurrences of the word form “the” and of the sentence initial form “The”. The disjunction operator is an infix operator which takes two regular expressions as its arguments. Due to the bracketing conventions for the disjunction operator, the above query is equivalent to

"the|The";

By inserting parentheses again, the query can be reformulated more shortly as

"(t|T)he";

3.2.4 Lists of alternative characters

By using a list of alternative characters, the last query can be again rewritten.

"[tT]he";

For example, you can search for all occurrences of single digits in the corpus by the query

"[0123456789]";

This will retrieve any of the following tokens “0”, “1”, “2”, ..., “9”. A shorter way to formulate the same query is

"[0-9]";
### 3.2.5 Unspecified character

Say, if you don’t know whether the correct spelling is “Velazquez” or maybe “Velasquez”, you would write 

"Vela[zs]quez";

But you could also use the *unspecified character* in the place of the list of alternative characters. This makes the query a bit more sloppy on the one hand, but on the other hand, this is more handy to write.

"Vela.quez";

The .-operator will match any character.

### 3.2.6 Optionality

You may want to find simultaneously the two word forms “walk” and “walks”. Both word forms are captured by the regular expression

"walk(s)?";

The *optionality operator* ? indicates that the preceding expression is optional. Since, by default, the ? operator takes the preceding character as its operand, the parentheses can be omitted in the above case.

"walks?";

However, in the query

"walk(ed)?";

which retrieves the occurrences of “walk” and those of “walked”, the parentheses cannot be omitted!

### 3.2.7 Iteration (Kleene star and Kleene plus)

A word like “walk” has several morphological variants: “walks”, “walked”, and “walking”. Being sloppy, we query for all word forms which start with the character sequence walk. This is expressed by

"walk.*";

The *Kleene star operator* * means that the preceding regular expression, here the unspecified character, can occur any number of times, or needn’t occur at all. Since this is a sloppy way to express our intended query, we get also matches like “walker”, “walkie-talkie” etc.

In the last query, the word form “walk” itself was a part of the query result. If you only want to see word forms which are strictly longer as walk itself, you have to use the *plus operator* + instead of the star *.
"walk.*";

The plus + works like the star *, but it requires that its argument expression occurs at least once.

It is a bit hard to think of natural language examples which match a regular expression where the Kleene operator takes a string of length 2 or longer as its argument. In the Penn Treebank corpus, the following query will match only the word ‘Honolulu’.

".*lu(lu)+.*";

3.2.8 Flags

Some common types of regular expressions can be expressed in a much shorter manner with the help of CQP/flags.

%d  “insert diacritics”
    It is sufficient to specify in the query the plain character without diacritics, but still all its occurrences with diacritics will be considered. E.g. our query for the word Spätzle will turn into:

"Spatzle" \%d;

%c  “case insensitive”
    Retrieve both upper and lower case variants of the query. Example:

"the" %c;

for searching “the” as well as “The”.

%l  “literal use”
    With this option, all the CQP operators in the query are interpreted literally.

"*" %l;

finds all occurrences of * in the corpus. This query is equivalent to

"\*";

As the %l option turns off both %d and %c, only the combinations %l, %c, %d and %cd are useful.
3.2.9 A nontrivial example

We will conclude this section with quite a nontrivial example of a regular expression. Let’s assume, we want to find occurrences of the German verb “treffen”. Since the German language has a rich inflectional morphology, many word forms are based on this stem:

The easiest way of rendering this list as a regular expression would be to write down a long disjunction of all the individual word forms. However, the query can become shorter (but maybe more opaque) based on the following observations.

- All word forms with the prefix treff are matched by the regular expression treff(e(nd(?)|s?t)?
- All word forms with the prefix trifff are matched by the regular expression trifff(s?t)?
- All word forms with the prefix traf are matched by the regular expression traf(s?t|en)?
- All word forms with the prefix träf are matched by the regular expression traf(en|s?t)?
- The word form getroffen is matched by the regular expression getroffen
- All word forms of the stem treffen may occur at the beginning of a sentence, so the initial character may be capitalized.

In total, we get the following regular expression

"[tT]reff(e(nd(?)|s?t)?|tT]rifff(s?t)?|tT]raf(s?t|en)?|tT]r\"af(en|s?t)?|getroffen";

3.3 String variables

So far, we have seen only regular expressions as queries for strings. However, in corpus linguistics, people often deal with word lists and don’t want to bother packing such a list into a regular expression. Therefore, CQP admits the definition and the use of string variables. A string variable takes a list of strings (or words) as its value. The name of string variable starts with the -symbol. For example, in order to define the string variable $colors as a list of the three strings red, green, and blue, you have to issue the followind define-command.

define $colors="red green blue";

Now, instead of writing a lengthy query like

"red|green|blue";
it is sufficient to say:

\$colors;

Note that the string variable must not be included in quotation marks! Otherwise, it would be mistaken for a regular expression.

You can add further elements to the value of a string variable by the use of the +=-operator.

define $colors += "yellow";

Elements can be removed with the help of the -=-operator.

define $colors -= "green";

After so many manipulations of this variable, we may want to check its current value:

show $colors;

red blue yellow

String variables are particularly useful, if the lists of tokens get longer. For this reason, the value of a string variable can be read from a file. The individual tokens must be listed in a one-word per line format. This means that the contents, say, of the file mydict could look as follows.

green
red
blue
yellow

The string variable $colors is set to the disjunction of these words by the following variant of the define-command.

define $verbs < "mydict";

Note that string variables can only stand for lists of tokens, not for regular expressions over strings.

### 3.4 Attribute Expressions

#### 3.4.1 Attributes

The examples in the last section referred to the words of a text. However, CQP supports the work with annotated corpora. The corpus positions of a corpus can be annotated with an unlimited number of attributes. Usually, each word defines a corpus position, whereas, for a speech corpus, corpus positions could be defined at the phoneme level. For CQP, the word form (or the phoneme) which is associated with a corpus position, is just one, albeit distinguished kind of positional attribute. This means that the query
"Clinton";

is just an abbreviation of its more formal equivalent:

[word = "Clinton"];  

The square brackets [ ] mark the beginning and the end of a query for a single corpus position. The =-symbol marks an attribute-value pair. It is a two-place operator which takes an attribute name (e.g. word) on its left side and an attribute value on its right side. Attribute values have to be string variables or regular expressions over character strings.

The Penn Treebank corpus is an example of an annotated corpus (or tagged corpus.) Its corpus positions come with part-of-speech tags ('pos tags'). In this tag set, the part-of-speech tag for determiners is DT. Hence, if we want to find all determiners in the UP corpus, we have to write the following query:

[pos = "DT"];  

Here is an example of a (non trivial) regular expression for the pos-attribute.

[pos = "N.*"];  

This query matches all corpus positions whose pos-value is in the set of 'noun tags' NN, NNS, NP, NPS. In order to see which one of the matching words comes with which pos-value, you can switch on the display for this attribute (see section 2.4.6) and have the result of the previous query displayed again.

show +pos;  
cat;

3: T/.TXT .PP/.PP Pierre/NP <Vinken/NP> ,/, 61/CD years/NNS old/
6: e/NP Vinken/NP ,/, 61/CD <years/NNS> old/JJ ,/, will/MD join/
12: , will/MD join/VB the/DT <board/NN> as/IN a/DT nonexecutive/

By the way, the distinguished attribute can be changed. For example, if your corpus is annotated with a lemma attribute and you are interested mainly in that attribute, you can change the value of the CQP variable DefaultNonbrackAttr in the following manner:

set DefaultNonbrackAttr lemma;

Then the query

"see";

will mean

[lemma = "see" ];
3.4.2 Boolean expressions over attribute-value pairs

Attribute-value pairs can be combined into Boolean expressions. CQP admits the usual logical operators: conjunction, disjunction, and negation.

Embedded Boolean expressions

As usual, parentheses (,) are used to mark an expression which is embedded into another Boolean expression. The parentheses help to specify the range and the precedence of the logical operators.

Conjunction

It is convenient to combine constraints on several attributes into a single query. For example, if we want to see only the uses of the word "rain" as a noun (in the UP-corpus), we need the conjunction operator &.

[word="rain" & pos="NN"];  

This attribute expression calculates the intersection of the results of the two queries

[word="rain"];  

and

[pos="NN"];  

Disjunction

An example for the use of the disjunction operator | in an attribute expression would be

[ word="the" | word="The" ];  

This query results in the set union of the results of the two queries

[word="the"];  

and

[word="The"];  

However, in the earlier sections of this chapter, we have seen more succinct ways to express the disjunctive query above. For example

"[tT]he";
Negation

When you want to judge the quality of an automatic part-of-speech tagger, you are looking for words which have been tagged in the wrong way. Astonishingly, although the word “the” is only used as a determiner (“DT”) in English, it occurs also with some other part-of-speech tags in the Penn Treebank corpus. So let’s search for those occurrences.

```
[word = "[tT]he" & !( pos = "DT" ) ];
```

The -operator takes a Boolean expression on its right side. In the case of the given query, logically, CQP calculates the intersection of the query result for the word “the” (resp. “The”) and the result of the query for all corpus positions which are labelled with a part-of-speech tag different from DT. Here are the first few lines of the result.

```
5909: entennial/NN year/NN ,/ <The/NP> Wall/NP Street/NP Journ
26347: , billed/VED as/IN ‘/‘ <The/NP> Practical/NP Journal/NP
50124: 6/CD editorial/NN ‘/‘ <The/NP> Ill/NP Homeless/NP ’/’/’
80051: P Jones/NP publishes/VBZ <The/NP> Wall/NP Street/NP Journ
259798: P Atwood/NP ’s/POS /‘/‘ <The/NP> Handmaid/NP ’s/POS Tale/
262883: es/NP ’/’/’ and/CC /‘/‘ <The/NP> Mary/NP Tyler/NP Moore/N
```

In the case of negated attribute-value pairs such as !(pos = "DT"), CQP offers an abbreviation, based on the -operator, the so-called value negation. The previous query can be equivalently written as

```
[word = "[tT]he" & pos != "DT"];
```

Negations of complex expressions are evaluated according to the well-known Boolean equivalences. This means that the three following queries are equivalent.

```
[ !(word = "water" | pos = "NN")];
[ !(word = "water") & !( pos = "NN")];
[ word != "water" & pos != "NN" ];
```

Operator precedence

The precedence properties of the (logical) operators are defined by the following list, i.e. if operator x is listed before operator y, operator x has precedence over y.

```
=, !=, !, & , |
```

For example,

```
[ ! word = "water" & ! pos = "NN" ];
```

disambiguates as

```
[ !(word = "water") & !( pos = "NN")];
```

Operators are evaluated from left to right.

x
Chapter 4

Access to sequences of corpus positions

This chapter describes how one can retrieve sequences of corpus positions. In chapter 3, we have learned about the retrieval of single corpus positions. The language for retrieving single corpus positions consists of attribute expressions, i.e. Boolean expressions over regular expressions over characters. Subsequently, attribute expression will often be called descriptions of corpus positions, or simply, corpus positions. Now, we scale up once more, by introducing Boolean expressions over regular expressions over attribute expressions. We will call them (sequence) patterns.

4.1 Regular expressions over attribute expressions

The language of regular expressions over attribute expressions includes the following operators: parentheses for marking embedded expressions, concatenation, disjunction, unspecified corpus position, optionality, Kleene star, and Kleene plus.

4.1.1 Embedded regular expressions

As usual, the parentheses (,) will mark embedded expressions.

4.1.2 Concatenation

Regular expressions over corpus positions are concatenated by simple juxtaposition. So, for example, the search for the string “Bill” followed by the string “Clinton” is triggered as follows

"Bill""Clinton";

Since the query refers to sequences of length 2, the match is also of length 2, i.e. there are two word forms between the angle brackets.

For the concatenation of corpus positions, blanks and even new lines don’t count. This means that you can format your query according to your taste, e.g.

"Bill" "Clinton";
or

UP> "Bill"
"Clinton";

Of course, the description of an individual corpus position can be any kind of attribute expression. E.g. if you want to find the proper name (NP) which follows the Christian name "Bill" in the UP corpus, type:

"Bill" [pos = "NP"];

Concatenated corpus positions can be concatenated with further corpus positions, and so on. E.g. a query for multiword proper names, which consist of three individual proper names is represented by

[ pos = "NP"] [ pos = "NP"] [ pos = "NP"];

Among others, it returns the following matches.

177: BP in/IN today/NN 's/POS <New/NP England/NP Journal/NP> of/IN Medicine/NP ,/,
270: sk/NN ,/ , , said/VBD <James/NP A./NP Talcott/NP> of/IN Boston/NP 's/POS D
276: P of/IN Boston/NP 's/POS <Dana-Farber/NP Cancer/NP Institute/NP> ./SENT Dr./NP

4.1.3 Disjunction

Certain multiword entity names have the following pattern: two individual proper names, possibly with the preposition "of" in between. With the help of the disjunction operator , this query is simply formulated by enumerating the two different shapes:

([ pos = "NP"] [ pos = "NP"] ) | ([ pos = "NP"] "of" [ pos = "NP"]);

Evaluation strategy

Whereas CQP enumerates all possible matches for a disjunctive regular expression over characters, CQP employs a (left-to-right) first match strategy for disjunctive regular expressions over corpus positions. This means the following: if the prefix of one of the disjuncts equals another disjunct, the longer disjunct will be ignored. I.e. in the query result, there will be no matches for the longer disjunct. - This applies only to the whole query, not to its embedded disjunctive expressions. For example, in the following query, the disjunct which encodes a sequence of three proper names (NP), is useless, since one of its prefixes is the other disjunct which asks only for two proper names. Hence, practically, albeit not logically, the query

([ pos = "NP"] [ pos = "NP"] ) | ([ pos = "NP"] [ pos = "NP"] [ pos = "NP"]);

is equivalent to the query

[ pos = "NP"] [ pos = "NP"];

This kind of incompleteness which is caused by the first match strategy applies to all the operations which will be introduced subsequently!
### 4.1.4 Unspecified corpus position

CQP also admits completely *unspecified* descriptions of corpus positions.

\[ \square; \]

This expression matches any position in the corpus.

### 4.1.5 Optionality

The *optionality operator* \(?\) makes the preceding expression optional. In this way, the above mentioned pattern of two individual proper names, possibly with the preposition “of” in between, can be formulated in a more succinct manner.

\[
[\text{pos} = "NP"] \text{ "of"? } [\text{pos} = "NP"];
\]

### 4.1.6 Iteration (Kleene star and Kleene plus)

Whereas \(\ast\) and \(\ast\) are the wild cards or iteration operators on the level of character strings, on the level of corpus positions, the corresponding wild cards are represented by \(\square\ast\) and \(\square\ast\), respectively. A naive way to search for cooccurrences of the verb “*give*” and its particle “*up*” would be the following query.

"*give* \(\square\ast\) "*up";

Since \(\square\ast\) matches any sequence of any length, we get matches like

- 51446: `<give the Transportation Department up>`
- 62276: `<give up>`
- 101737: `<give it up>`
- 132633: `<give the department ample power to block undesirable deals .

TXT .PP For years , a strict regimen governed the staff meetings at Nissan Motor Co. ’s technical center in Tokyo ’s western suburbs . .PP Employees wore identification badges listing not only their names but also their dates of hire . No one could voice an opinion until everybody with more seniority had spoken first , so younger employees -- often the most enthusiastic and innovative -- seldom spoke up>`

### 4.1.7 Restricted iteration

The third, very long match of the last query does not correspond to our intentions, when we want to find meaningful cooccurrences of the verb “*give*” and the particle “*up*”. If sentence-final punctuation is available generally in the corpus, we could include a negated attribute expression into the query in order to avoid that sentence boundaries are covered by the wildcard:

"*give* [pos \(!=\) "SENT"] \ast "*up";
However, in the case of typos in the query (e.g. `[pos!="SNET"]` *), an iteration expression may match very large sequences, e.g. the whole corpus - which may cause a disaster. For that reason, CQP offers various ways to represent restricted iterations: multipliers, the within operator, and the HardBoundary variable. Remember also that an iteration at the end of a pattern is restricted by the first-match strategy (see section 4.1.3). As an abbreviation for iterations at the beginning or the end of a pattern, CQP provides the expand operator.

**Multipliers**

The multiplier operator takes a sequence pattern \(X\) on its left side as its argument and comes in three shapes.

\[
X\{n\}
\]

means exactly \(n\) repetitions of the expression \(X\)

\[
X\{n,\}
\]

means \(n\) or more repetitions of \(X\)

\[
X\{n,m\}
\]

means at least \(n\) and at most \(m\) repetitions of \(X\)

Now, we can reformulate the last query in a more reliable manner. E.g. we can state that the corpus interval between the words "give" and "up" should not be longer than five corpus positions.

"give" □\{0,5\} "up";

By the way, the operators \(?, \ast, \text{and} +\) are short forms for certain uses of the multiplier operator.

\(X?\) is equivalent to \(X\{0,1\}\)

\(X\ast\) is equivalent to \(X\{0,\}\)

\(X+\) is equivalent to \(X\{1,\}\)

**Local upper bound of match size**

The maximal length of matches for a query can be restricted by using the within operator. It takes a sequence pattern as its left argument and a natural number (or more exactly: a distance expression) on its right side. For example,

"give" □\ast "up" within 7;

which is equivalent to our earlier query

"give" □\{0,5\} "up";
since the maximal number of consecutive corpus positions which can be covered is 8.

By the way, the following queries are notational variants of each other:

"give" □* "up" within 7;
"give" □* "up" within 7 word;
"give" □* "up" within 7 words;

Note that the cut operator (see section 2.4.4) must not precede the within operator. A correct example would be:

"give" □* "up" within 7 cut 5;

Here are a few more pairs of equivalent queries:

□* "Clinton" within 3;
□{0,3} "Clinton";
894370: <Clinton>
1681560: <currently owned by Clinton>
1681561: <owned by Clinton>
1681562: <by Clinton>

"Clinton" □{0,2};
"Clinton" □* within 2;

The latter pair of queries will only return matches with the single word “Clinton” due to the first-match strategy.

When the within operator applies to an expression with several iterations, an equivalent, plain sequence pattern is quite hard to formulate. For example, the following query restricts the whole match to a maximum size of 11 corpus positions.

"man" [[]* "is" □* [pos="VBN"] within 10;

In a naive, non-optimized formulation, this corresponds to a large disjunction of all the possible partitions of 11 corpus positions.

( ( "man" "is" □{0,8} [pos="VBN"] )
| ( "man" □{0,1} "is" □{0,7} [pos="VBN"] )
| ( "man" □{0,2} "is" □{0,6} [pos="VBN"] )
...
| ( "man" □{0,7} "is" □{0,1} [pos="VBN"] )
| ( "man" □{0,8} "is" [pos="VBN"] )
)

Fortunately, CQP does a certain amount of optimization for us, since otherwise the following match would occur several times in the result, since it is a match of each disjunct.

1452974: <man/NN ,/, is/VBZ attributed/VBN>
Global upper bound of match size

For people who don’t want to bother with figuring out the right kind of local restrictions, CQP comes with a default maximum size for matches, the so-called HardBoundary variable. You can check the value by stating

```plaintext
set HardBoundary;
```

or change it, e.g. by

```plaintext
set HardBoundary 20;
```

This will restrict the matches of subsequent queries to the maximal length of 21 corpus positions - unless a query makes use of the within operator. A within restriction makes CQP ignore the value of the HardBoundary.

Expansion of matches

Sometimes it is convenient to include a certain amount of the context into the match itself. If you want to include three corpus positions to both sides of the matches of the “Clinton” query, you would write:

```plaintext
[]{5} "Clinton" []{5};
```

But it may be more convenient to use the following, semantically equivalent syntax:

```plaintext
"Clinton" expand to 5;
```

Readability can be somewhat increased by using the keywords word or words:

```plaintext
"Clinton" expand to 5 word;
"Clinton" expand to 5 words;
```

If you only want to include left context into the match, the statement reads:

```plaintext
"Clinton" expand left to 5;
```

Similarly for 'expansion' on the right side:

```plaintext
"Clinton" expand right to 5;
```

Note, that, in the CQP syntax, the expand operator must neither precede the cut operator (see section 2.4.4) nor the within operator (see section 4.1.7).
4.2 Sequence patterns

The full language of sequence patterns allows for Boolean expressions over regular expressions over corpus positions. However, in the tradition of automata theory, CQP does not use the proper syntax of Boolean operators for that purpose. The Boolean operations of conjunction, disjunction, and negation, are rendered by their set-theoretical counterparts: intersection, union, and set difference.

4.2.1 Named queries

Regular expressions over corpus positions cannot be directly embedded into Boolean expressions, since the Boolean operators (or set operators) in sequence patterns take only query names as their arguments. Query names are similar to variables in programming languages. A query name is created by an assignment statement. CQP will assign automatically the (result of the) most recent query to the query name Last. If you want to refer to a query later on, you can assign the value of Last to some other query name, say MyQuery, e.g.

"Clinton";
MyQuery = Last;

The above two statements can be packed into a single one. The following CQP statement will run the query "Clinton" and assign its result to the query name MyQuery (and to Last !).

MyQuery = "Clinton";

The right hand side of an assignment statement may also include an expand operator whose left argument is a query name:

"Clinton";
Q1 = Last expand to s;

Remarks

- The assignment statement suppresses the output of the query result, although the AutoShow variable might have been switched on (see sections 2.4.1 and 2.4.2). Therefore, if you want to see the result of MyQuery, you have to say

  cat MyQuery;

- Query names must be distinct from attribute names, names of system corpora, CQP variables, and CQP commands. The names of system corpora are listed by the show command (see section 2.2). The reserved CQP symbols have been included in the index of this manual.

- Like in programming languages, an assignment statement will overwrite any previous value of the query name on the lefthand side of the = sign. If you have lost track of the query names which have been already introduced in the current CQP session or have been saved in an earlier session (see appendix C.1), you can use the show command (see section 2.2), or more precisely,
show sub;

to have the existing query names listed.

- Assignment does **not** mean identification. E.g. the `reduce` operation (see section 2.4.4) below will only affect the result of its argument `MyQuery` but not the result of `Last`, from which `MyQuery` inherited its value.

```plaintext
"Clinton";
MyQuery = Last;
reduce MyQuery to 5;
cat MyQuery;
cat Last;
```

### 4.2.2 Conjunction

The conjunction operator `intersect` (or `inter`) is a prefix operator which takes two query names on its right side as its arguments. For example:

```plaintext
UP> Q1 = "rain";
UP> Q2 = [pos = "NN"];
intersect Q1 Q2;
```

The above sequence of CQP statements is equivalent to the query in section 3.4.2:

```plaintext
UP> [word = "rain" & pos = "NN"];
```

Here is a more complicated example:

```plaintext
UP> Q1 = [pos = "JJ"] [pos = "NN"];
UP> Q2 = ["acid" "rain"];  
UP> intersect Q1 Q2;
```

which amounts to

```plaintext
UP> [word = "acid" & pos = "JJ"] [word = "rain" & pos = "NN"];
```

Note that the use of the intersection operator makes only sense if the queries denote the same type of sequences. E.g. the result of the intersection below is empty, since it asks for corpus positions which are simultaneously labeled as adjectives and as nouns - a condition which obviously never holds.

```plaintext
UP> Q1 = [pos = "JJ"];
UP> Q2 = [pos = "NN"];
UP> intersect Q1 Q2;
```
Similarly, the following query results in an empty set, since it looks for corpus intervals which are simultaneously of length 1 and of length 2.

```
UP> Q1 = [pos = "NP"]; 
UP> Q2 = [pos = "NP"] [pos = "NP"]; 
UP> intersect Q1 Q2;
```

Even more importantly, both arguments of the `intersect` operator (and the operators `join` and `diff` below) must have been evaluated on the same system corpus, i.e., the following statements will lead to the CQP warning “Original corpora of Q1 (UP) and Q2 (WSJ) differ.”

```
UP> Q1 = "rain"; 
UP> WSJ; 
WSJ> Q2 = "acid" "rain"; 
intersect Q1 Q2;
```

### 4.2.3 Disjunction

The disjunction operator `join` takes two query names as its arguments and creates the union of the results of both queries, for example:

```
Q1 = "acid" "rain" ; 
Q2 = "brown" "coal" ; 
join Q1 Q2;
```

Since regular expressions include a disjunction operation, the above query is logically equivalent to

```
( "acid" "rain" ) | ( "brown" "coal" );
```

Practically, there may be differences between the operators `|` and `join`, due to the first match strategy. Compare

```
Q1 = [pos = "JJ"] "rain" ; 
Q2 = [pos = "JJ"] "rain" "forest" ; 
join Q1 Q2;
```

with

```
( [pos = "JJ"] "rain" ) | ( [pos = "JJ"] "rain" "forest" );
```

The result of the `join` expression will include the match `<muddy rain forest>` whereas the result of the `|` expression will consist only of matches of length two.
4.2.4 Negation

The difference (or diff) operator takes also two arguments Q1 and Q2, but this time the order of arguments counts! The result of the second argument Q2 will be subtracted from the result of the first one Q1. Logically, this means (Q1 & not Q2). For example, if you want to find out which are the less common prepositions in the UP corpus, you could write:

Q1 = [pos = "IN"] ;
Q2 = "as|at|by|for|from|of|in|into|on|up|with" ;
diff Q1 Q2;

The above query can be rephrased in an equivalent manner by using the (value) negation of attribute expressions:

[ pos = "IN" & word != "as|at|by|for|from|of|in|into|on|up|with" ];

Here is an example where negation cannot be pushed down to the attribute expressions:

Q1 = [pos = "NP"] [pos = "IN"]? [pos = "NP"] ;
Q2 = [pos = "NP"] [pos = "NP"] ;
diff Q1 Q2;

The above query is just a complicated way to say:

[ pos = "NP"] [pos = "IN"] [pos = "NP"] ;

Note that if the order of arguments is inversed, the result will be quite different, i.e. in this case it will be empty, since the result of Q2 is included in the result of Q1.

Q1 = [pos = "NP"] [pos = "IN"]? [pos = "NP"] ;
Q2 = [pos = "NP"] [pos = "NP"] ;
diff Q2 Q1;

4.2.5 Embedded Boolean expressions

Since the operators intersect, join, and diff take only query names as their arguments, the proper embedding of other expressions is ruled out. However, fortunately, a Boolean expression may occur on the right side of an assignment statement. So, simply, assign the embedded expression to a (new) query name, and use that name instead of the expression itself. For example, the following statements describe the set of all adjective-noun sequences without the two sequences "acid rain" and "brown coal":

Q0 = [pos = "JJ"] [pos = "NN"] ;
Q1 = "acid" "rain" ;
Q2 = "brown" "coal" ;
Q3 = join Q1 Q2;
diff Q0 Q3;
Chapter 5

Access to structural information

CQP supports the access to two kinds of structural information with respect to corpora: predefined structures (structural annotations) and ad hoc structures (results of earlier queries).

5.1 Predefined structures

As we have seen in section 4.1.6, the unrestricted use of the wild card operator for corpus sequences does not make much sense, since it produces unintuitive results:

"give" []* "up";

...

132633: <give the department ample power to block undesirable deals .
.TXT .PP For years , a strict regimen governed the staff meetings
at Nissan Motor Co. 's technical center in Tokyo 's
western suburbs . .PP Employees wore identification badges
listing not only their names but also their dates of hire .
No one could voice an opinion until everybody with more seniority
had spoken first , so younger employees -- often the most
enthusiastic and innovative -- seldom spoke up>

In section 4.1.7, a number of ways have been shown how the span of a match can be restricted.
In the case that a corpus has been structurally annotated, the restrictions can refer to the these annotations. (The kind of annotations which a corpus provides can be checked by the info command, see section 2.2 and by the show command, see section 2.4.6.)

5.1.1 Use of structural tags in regular expressions

Since the Penn Treebank corpus is annotated with sentence boundaries (structural tag s), we can check, for example, which conjunctions (CC) occur at the beginning of a sentence:

<s> [pos="CC"] ;

Or, we can find out what kind of punctuation is used at the end of sentences:
The reference to structural tags may occur anywhere in a query. For example, we may look for nouns and determiners, separated by a punctuation mark and a sentence boundary:

\[\text{[pos="N.*"] [pos="SENT"] } \langle s \rangle \text{ [pos="DT"] } \langle /s \rangle;\]

or shorter:

\[\text{[pos="N.*"] [pos="SENT"] } \langle s \rangle \text{ [pos="DT"] } \langle /s \rangle;\]

Now, we can try also to restrict the cooccurrences of the words “give” and “up” to single sentences:

\(<s> \text{ []* "give" []* "up" []* </s>};\)

However, this delivers still plenty of unwanted matches, where one of the wild cards []* matches another <s> boundary:

132562: \langle<s>\rangle .PP ‘‘This ought to be subtitled the ‘Don’t let Frank Lorenzo take over another airline’ amendment,’’ said Rep. James Oberstar (D., Minn.), chairman of the House aviation subcommittee, who argued that the provision was unnecessary because the bill already would give the department ample power to block undesirable deals .</s>\langle<s>\rangle .TXT .PP For years , a strict regimen governed the staff meetings at Nissan Motor Co.’s technical center in Tokyo ’s western suburbs .</s>\langle<s>\rangle .PP Employees wore identification badges listing not only their names but also their dates of hire .</s>\langle<s>\rangle No one could voice an opinion until everybody with more seniority had spoken first , so younger employees -- often the most enthusiastic and innovative -- seldom spoke up at all .</s>\rangle

### 5.1.2 Structural restrictions for matches

Again, the within operator (see section 4.1.7) helps us to express exactly what we want, i.e. the restriction of cooccurrences of “give” and “up” to single sentences.

"give" []* "up" within s;

The argument after the within operator can also be a natural number followed by the name of a structural attribute. In this way, more general cooccurrence patterns can be investigated. For example, the following query looks for occurrences of the words “gain” and “profit” in an interval of three sentences:

\(("gain" []* "profit") \text{ | } ("profit" []* "gain") \text{ within 3 s;}\)

In the case that article boundaries are annotated like in the Wall Street Journal (WSJ), the above type of query can be made more meaningful:

WSJ> ("gain" []* "profit") \text{ | } ("profit" []* "gain") \text{ within article;}

35
5.1.3 Expansion of matches

Matches cannot only be expanded by a fixed number of corpus positions from their contexts (see section 4.1.7) but they can also be expanded up to structural boundaries. For example, the following query will return all the sentences (tag s) where the word "Clinton" occurs.

"Clinton" expand to s;

Alternatively, only left or right context can be incorporated:

"Clinton" expand left to s;
"Clinton" expand right to s;

Matches can also be expanded to cover several consecutive structures:

"Clinton" expand left to 2 s;
expands the match to the second sentence boundary on the left side. The query

"Clinton" expand to 2 s;
expands the match to the current sentence and adds one sentence on each side, so that the whole match then spans three sentences.

Note that the number of matches for the query "Clinton" may differ from the number of matches for "Clinton" expand to s; In the case that the word "Clinton" occurs more than once in the same sentence, this sentence will occur only once in the ‘expanded result’, whereas the result of the original query contains all the individual occurrences of the word “Clinton”. On the other hand, if the match of the initial query "Clinton" is not part of a sentence at all (but e.g. a part of a headline), it will still be part of the ‘expanded result’.

The match expansion to a structural boundary allows for the simulation of queries in the style of internet search engines. An internet-style query for documents which contain both the words “gain” and “profit” ("gain" AND "profit") does not refer to the relative order of the individual keywords, whereas the regular expressions in CQP do make reference to ‘word order’. For that reason, the query "gain" AND "profit" corresponds to a rather complicated regular expression in CQP:

```
WSJ> ("gain" [ ]* "profit") | ("profit" [ ]* "gain")
within article expand to article;
```

If we position the expand operator in a more ‘intelligent’ manner, the above query can be rephrased as

```
WSJ> Q1 = "gain" expand to article;
WSJ> Q2 = "profit" expand to article;
WSJ> intersect Q1 Q2;
```

This means that we ask for all articles Q1 which contain the word “gain”, all articles Q2 which contain the word “profit”, and obtain those articles which contain both words by a simple intersection of Q1 and Q2.
5.2 Ad hoc structures

In addition to the predefined structural annotation of a corpus, temporarily defined structural boundaries (*ad hoc structures*) can be exploited in queries.

5.2.1 Structural restrictions for matches

The class of attributive adjectives is defined by the syntactic context in which the adjective occurs, e.g. the sequence determiner (DT), adjective (JJ), and noun (NN).

```
[pos = "DT"] [pos = "JJ"] [pos = "NN"];
```

If we want to look only at the adjectives in the given context, we can express that in CQP as follows:

```
UP> NounPhrase = [pos = "DT"] [pos = "JJ"] [pos = "NN"];
UP> NounPhrase;
UP:NounPhrase[25913]> [pos = "JJ"];
```

This yields:

```
... 77: <high>
 204: <old>
 259: <useful>
 331: <different>
 426: <striking>
 526: <common>
 627: <gradual>
 696: <huge>
 870: <current>
 948: <average>
...
```

The command sequence

```
NounPhrase;
[pos = "JJ"];
```

tells CQP that the query [pos = "JJ"] has to find its matches *within* the boundaries defined by the query NounPhrase.

In order to get rid of the structural restriction, you have to select again the system corpus (see section 2.2), e.g.

```
UP:NounPhrase[25913]> UP;
UP>
```
Note that the `expand` operator and the insertion of an ad hoc structural boundary can be combined:

```
UP> "Clinton";
UP> Last expand to 5;
UP:Last[12]>
```

This is equivalent to

```
UP> "Clinton" expand to 5;
UP> Last;
UP:Last[12]>
```
Chapter 6

Access to multilevel annotation

The only kind of multilevel annotation which is supported by CQP is the alignment of two corpora, e.g. a text and its translation or a text and its phonetic transliteration.

6.1 Alignment constraints

CQP allows for queries which put simultaneously a constraint on the matches from a source corpus and on the corresponding corpus intervals from the target corpus, the corpus which is aligned with the source corpus. The alignment constraint, the constraint on the intervals from the target corpus, can only be global to query to the source corpus, i.e. alignment constraints cannot be embedded somewhere into queries.

The following examples are taken from the Hansard corpora (Canadian parliament protocols) which are available in French (HANSARD-F) and in English (HANSARD-E). Remember that in order to see the English counterparts, the alignment display has to be switched on (see section 2.4.6) by show +hansard-e;

HANSARD-F> "neuf" :HANSARD-E "new";

...  
1387939: <neuf>  
-->hansard-e: It is hard to renovate something that is already there, but if it is new buildings going up, it might be a good place to start.  
1414074: <neuf>  
-->hansard-e: From what I have heard, that is a slightly new angle.  
1557034: <neuf>  
-->hansard-e: That is a new wrinkle too that we have not heard in now nine provinces and two territories.  
...

The result of the above query is a list of pairs:

1. a match from the source corpus for the query "neuf"
2. the corpus interval (e.g. a sentence) from the target corpus
(a) which is aligned to that interval in the source corpus where the match for "neuf" occurs
(b) and which contains a match for the alignment constraint

In contrast to usual CQP patterns, alignment constraints can be negated by the operator . This operator constrains all the corpus positions in the aligned interval which is selected by the constraint on the source corpus. The following query searches for occurrences of "neuf" where there is no occurrence of "new" in the aligned corpus interval:

"neuf" :HANSARD-E ! "new";

The negation operator may occur only directly after the name of the aligned corpus.
The source corpus constraints and the alignment constraints may make use of the whole expressiveness of the CQP query language.

Remarks
An alignment constraint (whether negated or not) evaluates to false if a match from the source corpus has no aligned counterpart in the target corpus, e.g. in the case that there are ‘holes’ in the alignment.
The cut command considers only the matches for the constraint on the source corpus. So, when running queries on aligned corpora, a low bound for the cut operator may incidentally cut off all those source corpus matches with satisfiable alignment constraints. I.e. the query result may be empty.
Chapter 7

Inspection of query results

For the inspection by the human user, CQP offers alphabetical and frequency-based sorting of query results. In order to make the sorting routines more flexible, CQP allows for the marking of interesting corpus positions in a match or related to a match.

7.1 Marked corpus positions

By default, the sorting algorithms of CQP consider only the first position of a match or an interval of corpus positions at a fixed set-off from the beginning of a match. However, when a query includes iteration operators (see sections 4.1.6 and 4.1.7) there is no such fixed set-off, in general. In CQP, the set collocate command and its identical twin, the set keyword command, have to be used to mark ‘interesting’ corpus positions whose distance from the beginning of a match may vary. A set collocate command corresponds to a restricted kind of regular expressions plus an individual search strategy. For example, the following statements will create a query result for the regular expression "give" []{0,5} [pos="RP"] where the particles (RP) are marked.

"give" []{0,5} [pos="RP"];
set Last collocate rightmost [pos="RP"] within right 6 words from match inclusive;

The command set collocate takes five arguments:

The first argument (Last) is a query name.

The fourth argument is a way to encode a multiplier expression. ‘within right 6 words’ may mean []{0,5} between the first position of the match and the marked corpus position on the right side of the match. If the direction, left or right, is omitted, both sides of the match will be searched. If the number (6) is omitted, the default distance is 1. In the place of words, you can use word or any available structural annotation.

If the fifth argument has the value from match inclusive, the fourth argument is evaluated starting from the first position of the match. The value from match exclusive means that corpus positions are counted starting right after the match. The other possible values of the fifth argument are from collocate exclusive, from collocate inclusive, from keyword exclusive, and from keyword inclusive. The fifth argument is optional. When omitted, the default is from match exclusive.
The third argument of set collocate ([pos="RP"])) is an attribute expression which restricts the ‘interesting’ corpus position. Note that one cannot use a general pattern (for a sequence of corpus positions) at this place!

The second argument (rightmost) indicates the search strategy. Alternative values are leftmost, nearest, and farthest. The search strategy helps to disambiguate when there are several matches around the same corpus position, e.g.

"to" []{0,5} [pos = "DT"];
...
2008: tempts them <to return> to a heartland city for
2010: tempts them to return <to a> heartland city for
...

Remarks

- The set collocate operator suppresses the output of the query result although the AutoShow variable might have been switched on. Use the cat operator (see section 2.4.2) to have the result displayed.

- In contrast to the real multiplier operator, the set collocate command does not exclude those matches without a fitting ‘collocate’, it just marks the ‘collocates’ in those matches where they occur. If the initial match is too unrestricted, the set collocate will not make it more restricted! For example, the following statements will produce all matches for the word “give” where those particles are marked which are maximally five positions right of “give”.

"give";
set Last collocate leftmost [pos="RP"] within right 5 words;

- In the following example, the default query name Last will still be associated with the value of NounPhrase before set collocate and set keyword were carried out. I.e. in Last there won’t be anything marked even after all the statements below have been processed.

NounPhrase = [pos = "DT"] [pos = "JJ"] [pos = "NN"];
set NounPhrase collocate leftmost [pos = "JJ"] within right 1 words from match inclusive;

- Note the implications of the fact that the keyword ‘match’ in ‘from match inclusive’ means actually “the first position of the match”. This may lead to confusion when searching on the left side of the match. E.g. in order to have marked occurrences of the word “a” in the expression "to" []{0,5} [pos = "DT"] we might be tempted to say:

"to" []{0,5} [pos = "DT"];
set Last collocate rightmost "a" within left 5 words from match inclusive;

However, this will mark the rightmost occurrence of “a” on the left side of the second position of the match.

42
• When both sides are searched, the `set collocate` command may still be too underspecified to disambiguate a single position to be marked. But never mind, CQP will simply take the first fitting position from the left. E.g.

"Clinton";
set Last collocate farthest [] within 2 words from match exclusive;

44963: Utah, $15,000 fine; Clinton P. Hayne, New Orleans,
653115: on education, Gov. Bill Clinton of Arkansas announced ...
894320: , already buys gas from Clinton. PP Clinton said in
1681563: 's, currently owned by Clinton Holding

• In the third statement below, the first occurrence of the keyword collocate refers to a corpus position different from the corpus position designated by the second occurrence of collocate in the same line!

"Bill" "Clinton";
set Last collocate leftmost [] within right 1 words from match exclusive;
set Last collocate leftmost [] within right 1 words from collocate exclusive;

7.1.1 Two marked positions

One can combine the `set collocate` and the `set keyword` command in order to mark two ‘interesting’ positions simultaneously. The following statements mark the adjectives (JJ) in `NounPhrase` as ‘collocates’ and the nouns as ‘keywords’.

NounPhrase = [pos = "DT"] [pos = "JJ"] [pos = "NN"];
set NounPhrase collocate leftmost [pos = "JJ"] within right 1 words
from match inclusive;
set NounPhrase keyword leftmost [pos = "NN"] within right 2 words
from match inclusive;
cat NounPhrase;

76: <a high percentage>
203: <an old story>
258: <no useful information>
330: <a different type>
425: <a striking finding>
525: <the common kind>
626: <a gradual ban>
695: <a huge bin>
869: <the current yield>
947: <The average maturity>

7.2 Alphabetical sorting

(available in release 2.3)
The basic command to have a query result ordered alphabetically, is the statement `sort by 0;`. Try:

```
"Clint.*";
sort by 0;
```

371332: Lockman and third { <Clint> Hartung } as Bobby
44963: Utah, $15,000 fine; <Clinton> P. Hayne, New Orleans,
653115: on education, Gov. Bill <Clinton> of Arkansas announced

```
1826420: Hayes National Bank in <Clinton>. The bank holding
726164: Telephone Corp., of <Clintonville>, Wis., the
```

The `sort` command takes maximally five arguments. E.g. the statement `sort by 0` reads in its full beauty:

```
sort Last by 0 relative to match on word ascending;
```

The *first argument* (`Last`) is a query name. If the query name is omitted, its default is `Last`.

The *fourth argument* (`on word`) is the positional attribute whose value will serve as the basis for sorting. If omitted, the default value is `on word`. Here is an example where the verbs which start with *be* (and whose base forms are not equal to "be") are sorted according to the lemma value of the match.

```
[word = "be.*" & pos = "VB" & lemma != "be"];
sort by 0 on lemma;
```

The *third argument* (`relative to match`) indicates the (marked) corpus position, which serves as the basis to define the corpus interval to be sorted. Other values are `relative to collocate` and `relative to keyword`. The default value is `relative to match`. Again, ‘match’ means here “first position of the match”.

The *second argument* (`by 0`) designates the position, or more generally the corpus interval, which will be sorted. This corpus interval is defined relative to the corpus position indicated by the third argument. Examples:

The statements

```
"give" []{0,5} [pos="RP"];
sort by 5;
```

will sort on the basis of the fifth position from the beginning of the match, even if that position is not part of the match. Since this is probably not what you want, you should rather include a `set collocate` statement to mark the particle (`RP`).

```
"give" []{0,5} [pos="RP"];  
set Last collocate leftmost [pos="RP"] within right 6 words  
    from match inclusive; 
sort by 0 relative to collocate;
```
The matches where no particle is found in that range will be usually added to the end of the result.

Longer corpus intervals are represented by comma-separated integers. E.g. the statements below will sort the query result by considering the complete matches of length 2.

"Bill" [pos = "NP"];
sort by 0,1;

Negative integers can be used as to abbreviate certain kinds of set collocate expressions:

"Inc\." ;
sort by -1;

abbreviates

"Inc\." ;
set Last collocate rightmost [] within left 1 word;
sort by 0 relative to collocate;

The *fifth argument* lets you choose between ascending or descending (i.e. inverse) alphabetical sorting. The parameters can be abbreviated as *desc* and *asc*, respectively. The default sorting order is *ascending*.

Remarks

- The *sort* command displays its result immediately unless the *AutoShow* variable has been switched off.
- The *sort* command is destructive on its first argument, the query name whose result is to be sorted. Subsequent *cat* statements will always display the sorted result.

### 7.3 Frequency-based sorting

The simplest command to have a query result sorted with respect to the frequencies of the different matches reads:

"Clint.*";
group Last match word;

In total, the *group* command may take four arguments. E.g. the following *group* statement is essentially equivalent to the simpler one above:

group Last match word foreach match word cut 0;
The *first argument* (Last) is a query name.

The *second argument* (match word) defines the attribute (word) of a corpus position (here the first position of the match) whose values will be counted. Other designators for corpus positions are collocate and keyword (see section 7.1).

The *third argument* gives the justification for the name of this command. The following statements generate for each particle a list of verbs with the respective cooccurrence frequencies.

```plaintext
[pos="VB.*" & pos!="VB(P|Z)"] [0,5] [pos="RP"];
set Last collocate leftmost [pos="RP"] within right 6 words
    from match inclusive;
group Last match lemma foreach collocate word;
```

The keyword *foreach* is followed by a designator for a corpus position, i.e. *match*, *collocate*, or *keyword*, and a name of a positional attribute. Instead of the symbol *foreach*, one can also use ‘by’.

The *fourth argument*, which is optional, is the cut-operator. (The cut operator for group commands has been added in release 2.3.) It takes a natural number as its argument. This number determines the cut-off frequency for matches to be ignored.

**Remarks**

- The group command always outputs its result, regardless whether the AutoShow variable has been switched off or not. If the output of the group command to the standard output is annoying, it can be directed to a file or to a Unix pipe and be influenced by the PrintMode and PrintOptions similarly to the output of the cat command (see section 2.4.7, some effects are only part of release 2.3).

- The group command only shows the values and respective frequencies of the attributes of the corpus position or the two corpus positions under consideration. I.e. other details of the original matches are ignored and cannot recovered from the output of a group command.

- The group command always sorts by decreasing frequency.

- The cut and the foreach/by operators do not work together correctly.
Appendix A

The cqp and cqpcl commands

CQP can be invoked with the shell commands cqp (for interactive use) resp. cqpcl for non-interactive use. Upon startup, both commands read the values of certain Unix system variables (see section A.1) and evaluate the contents of the file "/.cqprc". This file may contain any number of valid CQP statements. As an alternative to the CQP commands, certain CQP variables can be set by command line options (see section A.2). In addition, the command cqpcl reads an arbitrary of command line arguments, which will be evaluated as CQP queries unless they are marked as command line options. The result will be written to stdout.

A.1 Environment variables for CQP

CQP uses the values of the following UNIX environment variables.

CORPUS_REGISTRATION
When CQP is started, the CQP variable Registry (see section 2.2) is set to the value of CORPUS_REGISTRATION. Usually, CORPUS_REGISTRATION is set by the system administrator.

CQP_LOCAL_CORP_DIR
This variable serves to initialize the CQP variable LocalCorpusDirectory (see section C.1).

PAGER
This is a generally used UNIX environment variable. Its value initializes the CQP variable Pager (see section 2.4.3).

A.2 Command line options

A.2.1 General options

Help
-h
The CQP help message will be displayed with short information about the usage of the command line options. This message will be also shown if CQP is called with incorrect parameter settings.

**Batch mode**

- **f File-Name**
  
  CQP will read its input from the file *File-Name* instead of interacting with the user. In order to make your CQP 'programs' more readable you can add *comments* in the usual shell style, i.e. prefixed with the #-symbol.

**Binary output**

- **i**
  
  With this option, CQP provides a simple protocoll for the communication with other applications. The query results which are represented as corpus position pairs are printed as binary coded integers.

**Protected mode**

- **x**
  
  The user will not be able to redirect the output of the *cat* and *group* commands into Unix pipes. Recommended for WWW-applications of CQP.

### A.2.2 Basic interaction

**Corpus selection**

- **D Corpus-Name**
  
  The corpus named *Corpus-Name* will be selected when CQP is started. Instead of using the command line option -D, you can set the CQP variable DefaultCorpus in your `.cqpcr` file, e.g. by the command

  ```
  set DefaultCorpus "UP";
  ```

  which will select the UP corpus upon start-up of CQP.

**Browsing method**

- **P BrowserName**
  
  For e.g. *BrowserName=more*, this amounts to (see section 2.4.3)

  ```
  set Pager more;
  ```
Context size

-\textit{W} \textit{Number}

-\textit{L} \textit{Number}

-\textit{R} \textit{Number}

E.g. for \textit{Number}=20, these options equal the following CQP statements (see section 2.4.5), respectively:

\begin{verbatim}
set Context 20;
set LeftContext 20;
set RightContext 20;
\end{verbatim}

A.2.3 Sequence patterns

Size of matches

-\textit{b} \textit{Number}

E.g. for \textit{Number}=50, the use of this option is equivalent to setting the \texttt{HardBoundary} variable (see section 4.1.7) to 50:

\begin{verbatim}
set HardBoundary 50;
\end{verbatim}
Appendix B

Special characters

Country-specific characters do not belong to the 7-bit ASCII standard. However, it is possible to enter these characters by using the corresponding (country-specific) \TeX commands. For example, the word “façade” is entered as

"fa\,çade";

\[\begin{array}{cccccc}
Ä & \text{"A} & Ä & \text{"A} & Ä & \text{"A} \\
È & \text{"E} & È & \text{"E} & È & \text{"E} \\
Í & \text{"I} & Í & \text{"I} & Í & \text{"I} \\
Ö & \text{"O} & Ö & \text{"O} & Ö & \text{"O} \\
Ü & \text{"U} & Ü & \text{"U} & Ü & \text{"U} \\
ä & \text{"{a}} & ä & \text{"{a}} & ä & \text{"{a}} \\
ë & \text{"{e}} & é & \text{"{e}} & é & \text{"{e}} \\
ï & \text{"{i}} & ì & \text{"{i}} & î & \text{"{i}} \\
ö & \text{"{o}} & ó & \text{"{o}} & ô & \text{"{o}} \\
u & \text{"{u}} & û & \text{"{u}} & û & \text{"{u}} \\
Č & \text{Č} & č & \text{č} \\
š & \text{š}
\end{array}\]
Appendix C

Incremental corpus exploration

E.g. if you are investigating the cooccurrence patterns of adjectives (JJ) and nouns (NN), it makes sense to ask first a very general query like

\[ Q1 = \text{[pos} = \text{"JJ"] [pos} = \text{"NN"]}; \]

and then to refine \( Q1 \) in various alternative manners. This will save computation time. Query names (like \( Q1 \)) have been introduced in section 4.2.1. Sections 4.2 and 5.2 showed how to make use of query results in subsequent queries. In addition, this chapter tells you how query results can be saved to hard disk and deleted from working memory.

C.1 Saving of intermediate results

If your work extends over several CQP sessions, you can save a query result into a file in CQP-encoded format (which should not be edited manually). The command

\texttt{UP> save;}

will save the result of the most recent query into the file \texttt{UP:Last} in the 'local corpus directory' (and possibly overwrite an older version of \texttt{UP:Last}). Whereas

\texttt{UP> save MyQuery;}

will save the result of the query named \texttt{MyQuery} as \texttt{UP:MyQuery}.

In order to carry out the \texttt{save} command successfully, the CQP variable \texttt{LocalCorpusDirectory} must have been set to the path of a directory with write access, e.g.

\texttt{set LocalCorpusDirectory "/corpora/subcorpora:/subcorpora";}

The \texttt{save} operation is illegal for system corpora.
C.2 Erasing of intermediate results

Query names produce overhead, since CQP has to manage the results which are associated with these names. Therefore, at times, it might make sense to remove query names from the CQP working memory. E.g., for the query names Q1 and Q2, this is done by the command

\texttt{discard Q1 Q2;}

Note that this only deletes the information about Q1 and Q2 from the CQP working memory, but it does \textbf{not} delete any saved query results (see section C.1) from your hard disk.
